Reasons for mutual interference between beam splitters

Multiphoton interference with a symmetric SU () beam splitter and the. Multiphoton interference with a symmetric SU (□□) beam splitter and the generalizat.

Key Takeaways

Mutual interference between beam splitters arises from the superposition of light waves or photon probability amplitudes, leading to constructive or destructive interference patterns that depend on relative phases and coherence.

Classical and Quantum Interference

When multiple beam splitters are used in an optical setup, such as a Mach-Zehnder interferometer, the output intensity and photon detection probabilities are determined by the interference of the split beams. Each beam splitter divides the incoming light into transmitted and reflected components, and when these components recombine at a subsequent beam splitter, their relative phases dictate whether interference is constructive or destructive. In classical optics, this results in intensity fringes, while in quantum optics, it affects the probability amplitudes for detecting photons at specific detectors.

Photon Effects

In the quantum regime, single photons interacting with multiple beam splitters exhibit non-classical interference. For example, in the Hong-Ou-Mandel (HOM) effect, two indistinguishable photons entering a balanced beam splitter simultaneously will "bunch" together, exiting through the same port and producing zero coincidence counts at separate detectors. When multiple beam splitters are arranged, such as in a Mach-Zehnder interferometer, the phase difference between paths controls the probability of photon detection at each output, and interference patterns emerge even with one photon at a time.

Multi-

Port and Multi-Core InterferenceAdvanced setups, including multi-port beam splitters or multi-core optical fibers, allow interference between photons from different input channels. Mutual interference in these systems can generate fourth-order interference effects, quantum correlations, and even non-classical states like entanglement or quantum discord. The interference depends on the relative phase, intensity ratios, and coherence between inputs, and careful control of these parameters can maximize or suppress correlations.

Practical Considerations

Phase control: Small phase shifts between paths can dramatically alter interference outcomes. Coherence: Mutual interference requires coherent or partially coherent sources; incoherent inputs reduce interference visibility. Detector placement: The spatial distribution of interference fringes affects where photons are detected, and total photon number is conserved even if intensity varies locally.

Beam splitter properties: Transmission/reflection ratios, polarization sensitivity, and internal multilayer interference can influence mutual interference patterns.

Summary

Mutual interference between beam splitters is a result of wave superposition or quantum probability amplitude interactions. In classical optics, it manifests as intensity fringes, while in quantum optics, it governs photon detection probabilities and can produce non-classical correlations. The effect is highly sensitive to phase differences, coherence, and beam splitter characteristics, making it a fundamental principle in interferometry, quantum computing, and photonic experiments.

Coherent states, beam splitters and photons

There is interference between coherent states. That interference can be understood classically, but, quantum-mechanically, is still between the different paths each photon in the coherent state can take.

Interference and the lossless lossy beam splitter

Two photons falling on a beam splitter from the same input arm are usually distributed between the outputs according to the laws of classical probability but this is not the case here.

Interacting electrons collide at a beam splitter

High-energy electrons that collide at a beam splitter repel each other because of strong Coulomb interactions, which could be harnessed for quantum information processing.
